The scientists analyzed 16,000 species and found that a species' geographic range was strongly correlated with its tolerance of drought and heat. "If your global model says that temperatures are going to increase in this area, you're going to see more species that are tolerant of that," said Katherine Joyce, the lead author of the research published in the current issue of Proceedings of the National Academy of Sciences. Climate change is likely to increase the intensity and frequency of droughts in much of the world. Joyce's findings indicate that species from hot, dry places will be hardest hit by global warming. In contrast, species that can survive and thrive in the temperate regions of the United States and Europe will likely be less affected by climate change. "This is good news for those who want to preserve natural

ecosystems in the face of changing climate,” she said. “But it’s a little scary for some people. This is very much an area of research where we’re learning that these impacts are going to be very severe.” Joyce and her colleagues analyzed the presence or absence of plant species in 3,100 species-area plots across the globe. Data on the locations of those plants, collected by others, were used to infer where those species might be likely to occur. The analysis showed that drought- and heat-tolerant species tend to occur in hotter, drier parts of the world, while species that can tolerate drought and heat tend to be more common in the temperate regions. “There are two types of species-specific responses to climate change: warming is either very good or very bad for them,” Joyce said. “But species that are able to tolerate drought and heat tend to be very well adapted to their local climate.” In a separate study, Joyce and her colleagues showed that climate change is likely to a1d647c40b
